Abstract:
Classical significance tests with fixed dimension are known to over-reject point null hypotheses in large samples due to the high levels of power they attain as the acceptance region shrinks with sample size for a given significance level. Relevant discussions on this issue include [1], [3], [5], and [7]. The need to find alternatives is evident in the present-day context, as the utility and the correct interpretation of classical tests is being debated, and there is concern about the frequent misuse and misinterpretation of classical measures of evidence (see, for example, [2], [9], [12], and [13]). Bayes factors, used extensively in both Bayesian model selection and hypothesis testing, are a popular alternative to classical significance tests. Bayesian methods, however, require the specification of prior distributions, and Bayes factors are known to depend rather strongly on prior distribution specification. This dependency does not disappear as the sample size increases, as it does in parameter estimation. Moreover, non-informative priors are often defined only up to a constant multiple, yielding indeterminate Bayes factors. To solve this indeterminacy, alternatives based on training samples have been suggested, including: fractional Bayes factors [10], intrinsic Bayes factors [4], expected-posterior priors [11], power-expected-posterior priors [8], and integral priors [6]. Using the aforementioned methods, we will derive default Bayes factors and prior distributions to be used in multinomial point null hypothesis testing, and assess and compare their properties and their performance on simulated data, as we intend to extend the application of default model selection methods to the problem of multinomial point null hypothesis testing.
